Abstract—MacKay-Neal (MN) and Hsu-Anastasopoulos (HA) low-density parity-check (LDPC) codes are known to achieve the capacity of memoryless binary-input symmetric-output channels under maximum likelihood (ML) decoding with bounded column and row weight in their associated parity-check matrices. Recently, Kasai and Sakaniwa showed that spatially coupled (SC) versions of the MN and HA LDPC codes have belief propagation (BP) iterative decoding thresholds that approach capacity on the binary erasure channel (BEC) as the coupling length increases.

In this paper, we extend the results of Kasai and Sakaniwa to the additive white Gaussian noise (AWGN) channel and show that the thresholds of the SC-MN and SC-HA ensembles approach capacity with bounded density as the coupling length increases, i.e., the number of edges per information bit approaches a finite value as the estimated BP threshold approaches the Shannon limit. We also perform an asymptotic weight enumerator analysis and show that, provided the density parameters are chosen to be sufficiently large, the SC-MN and SC-HA ensembles are asymptotically good. Further, for certain selections of parameters, some of these ensembles are shown to have both excellent thresholds and good distance properties.

I. INTRODUCTION

Ensembles of spatially coupled low-density parity-check codes (SC-LDPCs) can be obtained by terminating LDPC convolutional code ensembles [1]. The reduced check node degrees resulting from the termination of the convolutional codes have been shown to lead to substantially better belief propagation (BP) decoding thresholds compared to corresponding block, or uncoupled, code ensembles [1]–[6]. It has been proven analytically for the binary erasure channel (BEC) that the BP decoding thresholds of a class of (J,K)-regular SC-LDPPC ensembles achieve the maximum a posteriori probability (MAP) decoding thresholds of the corresponding (J,K)-regular LDPC block code ensembles [5]. This phenomenon has been termed “threshold saturation” and has recently been proven for general memoryless binary-input symmetric-output (MBS) channels [6].

As a result of threshold saturation, the (J,K)-regular SC-LDPC ensembles studied in [5] and [6] achieve capacity universally on MBS channels with BP decoding as the variable and check node degrees J and K increase, since, for an arbitrary MBS channel, the MAP thresholds of the corresponding block code ensembles improve to the Shannon limit [7]. However, the density of a rate $R = 1 - J/K$, (J,K)-regular LDPC code ensemble, defined as the number of edges per information bit, is given by $JK/(K - J)$, which is unbounded as $J,K \to \infty$.

In comparison to many other capacity approaching constructions, MacKay-Neal (MN) [8], [9] and Hsu-Anastasopoulos (HA) [10] LDPC codes can be shown to achieve capacity on MBS channels with bounded density under maximum likelihood (ML) decoding [10]–[12]. This is achieved by puncturing a number of the variable nodes in the Tanner graph of the code. MN codes are non-systematic LDPC codes, with two different edge types. HA codes, the duals of MN codes, are constructed by concatenating LDPC codes and low-density generator-matrix (LDGM) codes. In [13], Kasai and Sakaniwa showed that spatially coupled versions of the MN and HA LDPC codes have BP thresholds that approach capacity on the BEC as the coupling length increases.

In this paper, we extend the results of [13] to the additive white Gaussian noise (AWGN) channel and show that the BP thresholds of the SC-MN and SC-HA ensembles approach capacity with bounded density as the coupling length increases, i.e., the number of edges per information bit approaches a finite value as the estimated BP threshold approaches the Shannon limit. We also perform an asymptotic weight enumerator analysis and show that, provided the density parameters are chosen to be sufficiently large, the SC-MN and SC-HA ensembles are asymptotically good, i.e., the minimum distance typical of most members of the ensemble grows linearly with block length as the block length tends to infinity. Further, for certain selections of parameters, some of these ensembles are shown to have both excellent thresholds and large minimum distance growth rates.

II. PROTOGRAPH-BASED SPATIALLY COUPLED LDPC CODE ENSEMBLES

A. Protagraph construction of LDPC codes

A protograph [14] is a small bipartite graph $B = (V, C, E)$ that connects a set of $n_v = |V|$ variable nodes to a set of $n_c = |C|$ check nodes by a set of $E$ edges $E$. The protograph can be represented by a parity-check or base biadjacency matrix $B$, where $B_{x,y}$ is taken to be the number of edges connecting variable node $v_x$ to check node $c_y$. The parity-check matrix $H$ of a protograph-based LDPC block code can be created by replacing each non-zero entry in $B$ by a sum of $B_{x,y}$ permutation matrices of size $N$ and a zero entry by the $N \times N$ all-zero matrix. It is an important feature of this construction that each derived code inherits the degree distribution and graph neighbourhood structure of the protograph. The ensemble

This work was partially supported by NSF Grants CCF-0830650 and CCF-1165714.
of protograph-based LDPC codes with block length \( n = Nn_v \)
is defined by the set of matrices \( \mathbf{H} \) that can be derived from a
given protograph by all possible combinations of \( N \times N \) permutation matrices.

B. Spatially coupled protographs

SC-LDPC code ensembles can be constructed by coupling together several block code ensembles in a chain. Figure 1
shows representative Tanner graphs for (a) an LDPC block code ensemble, (b) an uncoupled chain of LDPC block code
ensembles, and (c) a SC-LDPC code ensemble.

![Tanner graphs](image)

For the \((3,6)\)-regular ensemble depicted in Fig. 1(a), the iterative decoding threshold for the BEC is \( \epsilon_{BP} = 0.4294 \).
Figure 1(b) shows a chain of \( L \) uncoupled \((3,6)\)-regular LDPC block code protographs. This figure corresponds to
block code transmission over time. Here, at each time unit \( t = 0, 1, \ldots, L-1 \), a block of data of length \( 2N \)
is transmitted and decoded independently. As a result of the noninteracting structure, each component behaves like the original protograph
in Fig. 1(a) and the BP threshold of each protograph is \( \epsilon_{BP} = 0.4294 \).

By coupling together the block code protographs, as demonstrated in Fig. 1(c) for \( L = 7 \), we obtain the protograph of a
SC-LDPC ensemble. Note that, by coupling the protographs in this way, we introduce a “structured irregularity” into
the coupled protograph; in this example all of the variable nodes still have 3 edge connections, however the check nodes
at the start and the end of the chain have fewer than 6 connections. For this \((3,6)\)-regular SC-LDPC code ensemble, we find that the threshold saturation effect improves the BP threshold from the uncoupled BP threshold \( \epsilon_{BP} = 0.4294 \) to a value numerically indistinguishable from the (optimal) MAP threshold \( \epsilon_{MAP} = 0.4881 \) as the coupling length \( L \) becomes sufficiently large.

The base matrix of a SC-LDPC ensemble is given by

\[
\mathbf{B}_{[0,L-1]} = \begin{bmatrix}
\mathbf{B}_0 & \cdots & \mathbf{B}_0 \\
\vdots & \ddots & \vdots \\
\mathbf{B}_{m_s} & \cdots & \mathbf{B}_{m_s}
\end{bmatrix}_{(L+m_s)b_v \times Lb_v} \tag{1}
\]

where \( m_s + 1 \) is the coupling width, and the \( b_v \times b_v \) component base matrices \( \mathbf{B}_i, i = 0, \ldots, m_s \) represent the edge connections from the \( b_v \) variable nodes in segment \( t \) to the \( b_t \) check nodes in segment \( t+i \). Starting from the base matrix \( \mathbf{B} \)
of a block code ensemble with design rate \( R = 1 - b_c/b_v \), one can construct the base matrix of a SC-LDPC ensemble that has (asymptotically, for large \( L \)) the same degree distribution and structure as the original ensemble. This is achieved by an edge spreading procedure (see [1] for details) that divides the edges from each variable node in the base matrix \( \mathbf{B} \)
among \( m_s + 1 \) component base matrices \( \mathbf{B}_i, i = 0, \ldots, m_s \), such that the condition \( \mathbf{B}_0 + \mathbf{B}_1 + \cdots + \mathbf{B}_{m_s} = \mathbf{B} \) is satisfied. For example, the \((3,6)\)-regular example given above can be constructed by spreading the edges of \( \mathbf{B} = \begin{bmatrix} 3 & 3 \\ 0 & 1 \end{bmatrix} \)
as \( \mathbf{B}_0 = \begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix}, \mathbf{B}_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \mathbf{B}_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \), where \( m_s = 2 \).

As a result of the boundary effects of spatial coupling, we observe some rate loss. Without puncturing, the design rate \( R_L \) of the SC-LDPC ensemble is equal to

\[
R_L = 1 - \left(\frac{L + m_s}{L}\right)(1 - R) .
\]

Note that, as the coupling length \( L \) increases, the rate increases and approaches the rate \( R = 1 - b_c/b_v \) of the block code ensemble as \( L \to \infty \).

III. SPATIALLY COUPLED MACKay-Neal and Hsu-Anastasopoulos LDPC CODE ENSEMBLES

We follow the construction of SC-MN and SC-HA protographs presented in [13]. The constructions are designed such that the SC-MN and SC-HA constructions have the same column-weight and almost the same row-weight distributions as the corresponding MN and HA construction, respectively. The protographs of SC-MN and SC-HA ensembles will be constructed from several simple terminated LDPC convolutional code base matrices.

A. SC-MN LDPC ensembles

We construct the protograph of a \((J, K, g, L)\) SC-MN LDPC ensemble by combining a \((J, K)\)-regular SC protograph of length \( 2L+1 \) with a \((g, g)\)-regular SC protograph of length \( J(2L + K)/K - g + 1 \) as follows. Let \( J = kK, K \geq 2, g \in [2, 2k+J], \) and \( L \geq 1, \) for \((J, K, g, L)\) SC-MN LDPC ensemble is obtained by concatenating two SC-LDPC base matrices \( \mathbf{V}_{[0,2L]} \) and \( \mathbf{S}_{[0,k(2L+K)-g]} \) in the form of (1), where the component submatrices \( \mathbf{V}_{i}, i = 0, \ldots, K-1 \), are each the all-ones matrices of size \( k \times 1 \) and the submatrices \( \mathbf{S}_{j}, j = 0, \ldots, g-1 \), are each the all-ones matrix of size \( 1 \times 1 \), respectively. Consequently, \( \mathbf{V}_{[0,2L]} \) has size \( k(2L+K) \times (2L+1) \) and \( \mathbf{S}_{[0,k(2L+K)-g]} \) has size \( k(2L+K) \times (k(2L+K) - g + 1) \). Then the base matrix of a \((J, K, g, L)\) SC-MN LDPC ensemble can be written as

\[
\mathbf{B}_{[0,L-1]}^{MN} = \begin{bmatrix}
\mathbf{V}_{[0,2L]} & \mathbf{S}_{[0,k(2L+K)-g]}
\end{bmatrix} ,
\tag{2}
\]

\(^1\)The value \( m_s \) denotes the syndrome former memory of the associated (unterminated) convolutional code ensemble.

\(^2\)Note that, as in the case of a single SC-LDPC protograph, we use \( L \) to refer to the length of a SC-MN protograph; however, the component SC-LDPC protographs will typically each have different lengths that are a function of the SC-MN protograph length \( L \).
where the variable nodes associated with $V_{[0,2L]}$ are punctured. The design rate of the ensemble is given by

$$ R_{MN}^{MN}(J,K,L) = \frac{2L - g + 2}{k(2L+1) + J - g - 1}, $$

where

$$ \lim_{L \to \infty} R_{MN}^{MN}(J,K,L) = \frac{1}{k}, $$

and the number of edges per information bit, or density, of members of the ensemble is given by

$$ \rho_{MN}^{MN}(J,K,L) = \frac{J(2L+1) + g(2kL + J - g + 1)}{2(L+1) - g}, $$

with

$$ \lim_{L \to \infty} \rho_{MN}^{MN}(J,K,L) = J + gk. $$

For example, consider the $(4,2,2,2)$ SC-MN LDPC ensemble. Here, $k = J/K = 2$, $R_{MN}^{MN}(4,2,2,2) = 4/11$, and $\rho_{MN}^{MN}(4,2,2,2) = 21/2$. The component submatrices are given as

$$ V_0 = V_1 = \left[ \begin{array}{c} 1 \\ 1 \end{array} \right] \quad \text{and} \quad S_0 = S_1 = \left[ \begin{array}{c} 1 \\ 1 \end{array} \right], $$

which are used to construct the base matrix of the $(4,2,2,2)$ SC-MN ensemble as follows:

$$ B_{MN}^{MN}[0,L-1] = B_{MN}^{MN}[0,4] = \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \quad \text{and} \quad S_{[0,10]} = \left[ \begin{array}{c} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{array} \right]. $$

The corresponding protograph is shown in Fig. 2. Note that the upper part of the protograph, corresponding to $V_{[0,4]}$, is a $(J = 4, K = 2)$-regular SC-LDPC chain of length $2L+1 = 5$, and the lower part, corresponding to $S_{[0,10]}$, is a $(g = 2, g = 2)$-regular SC-LDPC chain of length $J(2L+K)/K - g + 1 = 11$. 

![Fig. 2. Protograph representing a $(4,2,2,2)$ SC-MN LDPC code ensemble.](image)

Table I displays the BEC BP thresholds $\varepsilon^*$ calculated for a selection of $(4,2,2,L)$ SC-MN LDPC ensembles and the corresponding capacity values $\varepsilon_{Sh}$ for the given rate. The AWGN channel BP thresholds obtained for both the $(4,2,2,L)$ and $(6,3,2,L)$ SC-MN ensembles are shown in Fig. 3.3

![Table I](image)

where $0$ is the all-zeros matrix of size $(2L+J) \times (j(2L+1)+g-1)$, $I$ is the identity matrix of size $(j(2L+1)+g-1) \times (j(2L+1)+g-1)$, and the variable nodes associated with the left submatrix are punctured. The design rate of the ensemble is given by

$$ B_{HA}^{HA}[0,L-1] = \left[ \begin{array}{ccc} F_{[0,2L]} \\ S_{[0,j(2L+1)-1]} \end{array} \right], $$

where $F_{[0,2L]}$ has size $(2L+J) \times j(2L+1)$ and $S_{[0,j(2L+1)-1]}$ has size $j(2L+1)+g-1 \times j(2L+1)$. Then the base matrix of a $(J,K,L)$ SC-HA ensemble can be written as

$$ B_{HA}^{HA}[0,L-1] = F_{[0,2L]} S_{[0,j(2L+1)-1]}, $$

is some rate loss for finite $L$. The rates $R_{MN}^{MN}(4,2,2,L)$ and $R_{MN}^{MN}(6,3,2,L)$ increase monotonically and tend to $1/k = 1/2$ as $L \to \infty$. The densities $\rho_{MN}^{MN}(4,2,2,L)$ and $\rho_{MN}^{MN}(6,3,2,L)$ decrease monotonically, and tend to $J + kg = 8$ and $J + kg = 10$ as $L \to \infty$, respectively, i.e., the density is bounded. We find that, for both the BEC and the AWGN channel, the iterative decoding thresholds converge to a constant value as $L$ gets sufficiently large and that the gap to capacity decreases with increasing $L$. Moreover, the obtained thresholds are close to capacity in the limit of large $L$.

### B. SC-HA LDPC ensembles

In a similar fashion to the SC-MN LDPC ensembles, we construct the protograph of a $(J,K,L)$ SC-HA LDPC ensemble using a $(J,K)$-regular SC protograph of length $2L+1$ and a $(g,g)$-regular SC protograph of length $K(2L+1)/J - 1$ as the major components. Let $K = j J$, $J,K,g \geq 2$, and $L \geq 1$, for $J,K,g,L,j \in \mathbb{Z}$. Suppose that we construct two SC-LDPC base matrices $F_{[0,2L]}$ and $S_{[0,j(2L+1)-1]}$, in the form of (1), where the component submatrices $F_j$, $i = 0, \ldots, K - 1$, are each the all-ones matrix of size $1 \times j$ and the submatrices $S_j$, $j = 0, \ldots, g - 1$, are each the all-ones matrix of size $1 \times 1$ as for the MN codes. Consequently, $F_{[0,2L]}$ has size $(2L+J) \times j(2L+1)$ and $S_{[0,j(2L+1)-1]}$ has size $j(2L+1) + g - 1 \times j(2L+1)$. Then the base matrix of a $(J,K,L)$ SC-HA ensemble can be written as

$$ B_{HA}^{HA}[0,L-1] = \left[ \begin{array}{ccc} F_{[0,2L]} \\ S_{[0,j(2L+1)-1]} \end{array} \right], $$

3The (estimated) values obtained for the BP thresholds on the AWGN channel were computed using the RRA method [15].
where
\[ R^{HA}(J, K, g, L) = \frac{(j-1)(2L+1) - J + 1}{j(2L+1) + g - 1}, \]
and the density of members of the ensemble is given by
\[ \rho^{HA}(J, K, g, L) = \frac{j(j+g+1)(2L+1) + 2L - J}{j(2L+1) - 2L - J}, \]
with
\[ \lim_{L \to \infty} \rho^{HA}(J, K, g, L) = \frac{j(j+g+1)}{j - 1}. \]

For example, consider the (2, 4, 2, 2) SC-HA ensemble. Here \( j = K/J = 2 \), \( R^{HA}(2, 4, 2, 2) = 4/11 \), and \( \rho^{HA}(2, 4, 2, 2) = 51/4 \). The component submatrices are given as
\[ F_0 = F_1 = \begin{bmatrix} 1 & 1 \end{bmatrix} \quad \text{and} \quad S_0 = S_1 = \begin{bmatrix} 1 \end{bmatrix}, \]
which are used to construct the base matrix of the (2, 4, 2, 2) SC-HA ensemble
\[ B^{HA}_{[0, L-1]} = B^{HA}_{[0, 1]} = \begin{bmatrix} F_0[J+1]_{6 \times 10} & 0_{6 \times 11} & I_{11 \times 11} \end{bmatrix}. \]

The corresponding protograph is shown in Fig. 4. Here, the top part of the protograph, corresponding to \( F_{[0,4]} \), is a \( (J = 2, K = 4) \)-regular SC-LDPC chain of length \( 2L + 1 = 5 \), the middle part, corresponding to \( S_{[0,9]} \), is a \( (g = 2, g = 2) \)-regular SC-LDPC chain of length \( j(2L+1) = 10 \), and the bottom part, corresponding to the appended identity matrix \( I \), contains the variable nodes to be transmitted over the channel.

Table II displays the BEC BP thresholds \( \varepsilon^* \) calculated for a selection of (2, 4, 2, L) SC-HA LDPC ensembles. The rate \( R^{HA}(2, 4, 2, L) \) increases monotonically and tends to \( (j-1)/j = 1/2 \) as \( L \to \infty \). The density \( \rho^{HA}(2, 4, 2, L) \) decreases monotonically and tends to \( j(j+g+1)/(j-1) = 10 \) as \( L \to \infty \), i.e., the density is bounded. Note that \( R^{HA}(2, 4, 2, L) = R^{MN}(4, 2, 2, L) = 2L/(4L+3) \); however, we see that the density of the SC-HA ensemble is larger.

From Fig. 3, we observe that the thresholds obtained for the (2, 4, 2, L) SC-HA LDPC ensembles on the AWGN channel show a significant gap to capacity. However, the thresholds of the (3, 6, 2, L) SC-HA LDPC ensembles display similar characteristics to the SC-MN ensembles and converge to a constant value close to capacity in the limit of large \( L \).

IV. MINIMUM DISTANCE ANALYSIS OF SC-MN AND SC-HA LDPC ENSEMBLES

In this section, we study the minimum distance of SC-MN and SC-HA LDPC ensembles. The asymptotic spectral

shape function of a code ensemble is given by \( r(\delta) = \lim_{n \to \infty} \sup \ r_n(\delta) \), where \( r_n(\delta) = \ln(n) / n \), \( \delta = d/n \), \( d \) is the Hamming weight, \( n \) is the block length, and \( A_d \) is the ensemble average weight distribution. Suppose that the first positive zero crossing of \( r(\delta) \) occurs at \( \delta = \delta_{min} \). If \( r(\delta) \) is negative in the range \( 0 < \delta < \delta_{min} \), then \( \delta_{min} \) is called the minimum distance growth rate of the code ensemble. By considering the probability \( P(d < n\delta_{min}) \leq \sum_{d=1}^{n\delta_{min}-1} A_d \), it is clear that, as the block length \( n \) becomes sufficiently large, if \( P(d < n\delta_{min}) \ll 1 \), then we can say with high probability that a randomly chosen code from the ensemble has a minimum distance that is at least as large as \( n\delta_{min} \), i.e., the minimum distance increases linearly with block length \( n \). We refer to such an ensemble of codes as asymptotically good. The asymptotic spectral shape function \( r(\delta) \) of a protograph-based LDPC code ensemble can be calculated using the techniques presented by Divsalar et al. in [16].

A. Asymptotic distance analysis of SC-MN LDPC ensembles

Consider the (2, 4, 2, 2) SC-MN LDPC code ensemble previously discussed in Section III-A. The asymptotic spectral shape function for this ensemble is plotted in Fig. 5. We see that this ensemble is asymptotically good and that the minimum distance growth rate is \( \delta_{min} = 0.022 \).

![Fig. 5. Asymptotic spectral shape functions for the (2, 4, 2, 2) and (6, 3, 2, 2) SC-MN LDPC code ensembles.](image-url)

As we increase the coupling length \( L \), the rate increases, and the calculated BP thresholds get closer to capacity (see Table I and Fig. 3). The minimum distance growth rates, on the other hand, decrease with \( L \), as shown in Fig. 6 for \( L = 2, 3, \ldots, 8 \). Numerically, it becomes problematic to evaluate \( \delta_{min} \) for large values of \( L \); however, it is clear from the structure of the ensembles that the growth rates continue to decrease and tend to zero in the limit of large \( L \) if the coupling width is fixed.

Now consider increasing the density of the punctured variable nodes. The asymptotic spectral shape function for the
(6, 3, 2, L) SC-MN code ensemble is plotted in Fig. 5. We see that this ensemble is asymptotically good and that the minimum distance growth rate is significantly larger than for the (4, 2, 2, L) SC-MN code ensemble. Fig. 6 shows the minimum distance growth rates obtained for the (6, 3, 2, L) SC-MN ensembles for \( L = 2, 3, \ldots, 8 \). We observe a significant increase in the growth rates by increasing \( J \) and \( K \) while maintaining thresholds close to capacity (see Fig. 3). Analogously to \((J, K)\)-regular LDPC block code ensembles, we expect to observe increased minimum distance growth rates as we continue to increase \( J \) and \( K \).

B. Asymptotic distance analysis of SC-HA LDPCC ensembles

Consider the \((2, 4, 2, L)\) SC-HA LDPCC code ensemble previously discussed in Section III-B. The asymptotic spectral shape function for this ensemble is plotted in Fig. 7 along with the results for coupling lengths \( L = 1 \) and \( L = 4 \). The asymptotic spectral shape functions for these ensembles indicate that they are not asymptotically good. (Recall also that the AWGN channel thresholds displayed a significant gap to capacity for these ensembles (see Fig. 3).)

Fig. 6 displays the calculated growth rates for several \((3, 6, 2, L)\) SC-HA LDPCC ensembles. We observe that, by increasing the density of the punctured variable nodes, in addition to obtaining BP thresholds close to capacity for both the BEC and the AWGN channel, the SC-HA LDPCC ensembles are asymptotically good. Comparing the \((6, 3, 2, L)\) SC-MN ensembles and \((3, 6, 2, L)\) SC-HA ensembles, we find that the rates of both families of SC-LDPCC ensembles approach \( 1/2 \) with BP thresholds close to capacity; however, the minimum distance growth rates of the SC-HA codes are larger, which can be attributed in part to their higher density.

V. CONCLUSIONS

In this paper, we have performed an asymptotic analysis of spatially coupled MacKay-Neal and Hsu-Anastasopoulos LDPC codes. We demonstrated that, for both the BEC and the AWGN channel, the BP thresholds of the SC-MN and SC-HA ensembles are close to capacity with bounded density as the coupling length increases, i.e., the number of edges per information bit approaches a finite value as the estimated BP threshold approaches the Shannon limit. By performing an asymptotic weight enumerator analysis, we also showed that, provided that the density parameters are chosen to be sufficiently large, the SC-MN and SC-HA ensembles are asymptotically good. Further, for certain selections of parameters, some of these ensembles are shown to have both excellent thresholds and large minimum distance growth rates.
